SUMMARY

The exosome complex plays a central and essential role in RNA metabolism. However, comprehensive studies of exosome substrates and functional analyses of its subunits are lacking. Here, we demonstrate that as opposed to yeast and metazoans the plant exosome core possesses an unanticipated functional plasticity and present a genome-wide atlas of *Arabidopsis* exosome targets. Additionally, our study provides evidence for widespread polyadenylation- and exosome-mediated RNA quality control in plants, reveals unexpected aspects of stable structural RNA metabolism, and uncovers numerous novel exosome substrates. These include a select subset of mRNAs, miRNA processing intermediates, and hundreds of noncoding RNAs, the vast majority of which have not been previously described and belong to a layer of the transcriptome that can only be visualized upon inhibition of exosome activity. These first genome-wide maps of exosome substrates will aid in illuminating new fundamental components and regulatory mechanisms of eukaryotic transcriptomes.

INTRODUCTION

The exosome is an evolutionarily conserved macromolecular complex that mediates numerous reactions of 3′–5′ RNA processing and degradation and is essential for viability (Estevez et al., 2003; Mitchell et al., 1997). Loss of any individual subunit of its nine-component core is lethal in *S. cerevisiae* and causes near-identical profiles of RNA-processing defects (Allmang et al., 1999a, 1999b). Moreover, X-ray crystallographic analysis of the human exosome indicates that all nine core subunits are required for its integrity (Liu et al., 2006).

The salient feature of the exosome core is the hexameric ring defined by heterodimers of the RNase PH domain-type proteins RRP41-RRP45, MTR3-RRP42, and RRP43-RRP46. These heterodimers are bridged on one side by three subunits containing S1 and KH domains: RRP40 links RRP45 and RRP46, RRP4 interacts with RRP41 and RRP42, and CSL4 contacts MTR3 and RRP43. Surprisingly, all six RNase PH-type proteins in yeast and human complexes are catalytically inactive and serve to mediate interactions with RRP44 (Dis3), a 3′–5′ hydrolytic RNase responsible for most if not all of the catalytic activity of the yeast exosome (Dziembowski et al., 2007; Liu et al., 2007). In contrast, the RRP41 exosome subunit in the plant lineage retained its catalytic competence (Chekanova et al., 2000). Furthermore, RRP44 is stably associated with the core complex in yeast and *Drosophila* but not in human and *T. brucei* (Chen et al., 2001; Estevez et al., 2001, 2003). These

observations hint at a yet to be explored diversity of structure-function relationships in the exosome complex.

Many auxiliary factors interact with the exosome and facilitate its functions. Most of its cytoplasmic activities, such as homeostatic mRNA turnover, decay of unstable mRNAs, nonsense-mediated mRNA decay, as well as the degradation of the mRNA fragments derived from endonucleolytic cleavage by RISC or from no-go decay, are mediated by the SKI2/SKI3/SKI8 complex and the SKI7 protein (reviewed in Houseley et al., 2006). The exosome also has numerous targets in the nucleus. The nuclear exosome is remarkably versatile and is able to carry out precise 3′ end processing of the 5.8S rRNA precursor (Allmang et al., 1999a) but also completely degrades the external transcribed rRNA spacer (Allmang et al., 2000), aberrant pre-rRNAs, pre-mRNAs, and pre-tRNAs (Bousquet-Antonelli et al., 2000; Kadaba et al., 2004, 2006; Libri et al., 2002; Torchet et al., 2002), as well as the normal mRNAs trapped in the nucleus (Das et al., 2003). These processing and degradation activities require distinct auxiliary factors: the putative RNA-binding protein LRP1 participates in the processing of stable RNAs (Mitchell et al., 2003; Peng et al., 2003), while the RNase D-like protein RRP6 is required for all activities of the nuclear exosome. In addition, nuclear RNA degradation is facilitated by the TRAMP (TRF4/5-AIR1/2-MTR4 polyadenylation) complex, which helps recruit the exosome to the various aberrant RNAs (LaCava et al., 2005; Vanacova et al., 2005; Wyers et al., 2005).

Although the exosome is positioned at the nexus of cellular RNA transactions, the extent of conservation of structure-function relationships and the roles of its individual subunits across the phylogenetic spectrum remain unknown. Additionally, elucidation of the mechanistic basis of exosome essentiality is hampered by its functional versatility. Furthermore, exosome substrates have yet to be comprehensively identified in any system, as even the most extensive datasets available only address its nuclear-specific functions and/or are based on microarray platforms that are not genome wide and/or not strand specific (Davis and Ares, 2006; Houalla et al., 2006; Wyers et al., 2005). Here, we present evidence for a unique subfunctionalization of the individual subunits of the plant exosome core and widespread oligoadenylation- and exosome-mediated RNA quality-control pathways in plants. Further, we report the first high-resolution genome-wide map of exosome targets. These targets include multiple classes of stable structural RNAs, a select subset of mRNAs, primary microRNA (pri-miRNA) processing intermediates, tandem repeat-associated siRNA precursor species, as well as numerous noncoding RNAs, many of which can only be revealed through repressing the exosome.

RESULTS AND DISCUSSION

### Composition of the *Arabidopsis* Core Exosome
Previously, we demonstrated that *Arabidopsis thaliana* RRP4 and RRP41 proteins physically interact and reside in a high-molecular-weight complex in planta (Chekanova et al., 2000, 2002). To elucidate its composition, we generated transgenic plants expressing either TAP-tagged RRP4 or RRP41 at physiological levels in *rrp4-1* or *rrp41-1* mutant plants, respectively. TAP-tagged RRP4 and RRP41 fully rescued the lethal phenotypes of their corresponding null alleles. TAP-tagged complexes were purified, and polypeptides shared between RRP4-TAP and RRP41-TAP samples but absent from the wild-type (WT) sample were subjected to MALDI and MS/MS analyses. Nine polypeptides corresponding to known subunits of the exosome core were identified: S1 and/or KH domain-containing subunits RRP4, RRP40A, and CSL4 as well as the RNase PH-type subunits RRP41, RRP42, RRP43, RRP45B, RRP46, and MTR3 (Figure 1 and Table S1 available online).

In the case of subunits encoded by duplicated genes, only RRP40A and RRP45B were identified. This may be due to differences in the expression patterns and/or levels between the members of these gene pairs (Hooker et al., 2007). RRP6, which is restricted to a nuclear form of the exosome (Allmang et al., 1999b; Brouwer et al., 2001; Graham et al., 2006) and is likely underrepresented in our preparations, was also absent. On the other hand, the absence of RRP44, which is responsible for most if not all of the catalytic activity of the core exosome in yeast and humans, may reflect a genuine species-specific difference in the functional architecture of the exosome since the *Arabidopsis* RRP41 subunit is unique in retaining its full catalytic activity (Chekanova et al., 2000).

Mutations in the Core Subunits of *Arabidopsis* Exosome Cause Unique Phenotypes
To determine the consequences of losing specific exosome components on plant development, we characterized transfer-DNA (T-DNA) insertional alleles in several core subunits of the *Arabidopsis* exosome. In yeast, the CSL4 subunit is essential for viability (Allmang et al., 1999b; Baker et al., 1998), and X-ray crystallographic analysis of the human exosome predicts that all of its core subunits are critical to maintaining structural integrity and functionality of the complex (Liu et al., 2006). In marked contrast, we found that neither integrity nor function of the *Arabidopsis* exosome was significantly compromised by loss of CSL4. First, neither *csl4-1* nor *csl4-2* (a confirmed null allele) mutant plants manifested any discernible phenotype (Figure S1). Second, size fractionation demonstrated that the *Arabidopsis* exosome complex lacking CSL4 remained nearly intact (Figure 1C). Furthermore, tiling microarray analyses (below) revealed that loss of CSL4 affects only a subset of exosome targets (Figure S2 and Tables S2 and S3). In contrast, *Arabidopsis* RRP41 was essential for development of the female gametophyte, an eight-celled haploid structure derived from the primary product of female meiosis. While the *rrp41-1* mutant allele was normally transmitted through the male parent, it was not transmitted through the female (n = 194), and selfed *rrp41/RRP41* heterozygotes produced

Figure 1. Compositional Analysis of *Arabidopsis* Exosome

(A) TAP-tagged preparations from RRP4-TAP, RRP41-TAP, and WT lines. Exosome subunits identified by MS/MS are indicated. Major bands shared between the WT, RRP4-TAP, and RRP41-TAP samples correspond to TEV protease and a common contaminant.

(B) Exosome subunit homologs encoded in the *Arabidopsis* genome; subunits identified in TAP-tagged preparations are shaded.

(C) *Arabidopsis* RRP41 protein (27 kDa) cosediments with a complex of >210 kDa in both Ws and *csl4-2* extracts (calculated molecular weight [MW] of *Arabidopsis* exosome, based on the results of MS/MS, is 274 kDa).

seeds and aborted ovules in a 1:1 ratio (Figures 2A and S3; three independent *rrp41* alleles showed identical phenotypes). Furthermore, the resulting progeny segregated 1:1 for WT and heterozygous plants. The mutant female gametophytes arrested (n = 422) after the first mitosis (two-nucleate stage, 43.1%; Figures 2B and 2C) and less frequently at one-nucleate (1.4%), four-nucleate (3.3%), or later stages (3.0%).

Finally, loss of RRP4 resulted in an additional unique phenotype. Specifically, *rrp4-1* mutant seeds arrested at early stages of embryogenesis (Figures 2D and S4A–S4E). By the time WT progeny seeds of *rrp4-1/RRP4* plants reached the heart or torpedo stages of embryogenesis, 30% of the *rrp4-1/rrp4-1* progeny contained two-cell embryos, 0.5% undivided zygotes, and 3% had embryos at the early globular stage (n = 393). Analysis of stage-specific markers confirmed that *rrp4-1* seed morphology faithfully reflects their developmental timing (Figures S4F and S4G). The *rrp4-1* mutant endosperm developed to varying degrees but never past the cellularization stage (Figures S4B–S4D). These phenotypes cosegregated with the T-DNA genetic lesion, which was confirmed to be a null mutation using an SNP-based assay

(Figure 2E), and were fully rescued by the WT and TAP-tagged *RRP4* transgenes. In light of the recent findings that loss of the *Arabidopsis* mRNA decapping complex results in seedling lethality (Goeres et al., 2007; Xu et al., 2006), the phenotype of *rrp4-1* mutant seeds suggests a more general function for RRP4 in postzygotic development, which is consistent with its broad substrate range revealed by tiling microarray analyses (below). In summary, the distinctiveness of the phenotypes of *csl4*, *rrp4*, and *rrp41* mutant plants and their associated molecular signatures (below) indicate that the individual subunits in the *Arabidopsis* exosome core make nonequivalent contributions to its integrity and function. These findings set the plant exosome complex apart from those analyzed so far in other systems.

High-Definition Global Analysis of *Arabidopsis* Exosome Targets

To address the functions of RRP4 and RRP41 during vegetative growth, we engineered an estradiol-inducible RNAi (iRNAi) system (see Experimental Procedures). Growing these transgenic plants on estradiol-containing medium induced the RNAi-mediated knockdown of
Figure 2. Characterization of the Exosome Mutant Alleles

(A–C) Semisterility (A) and terminal arrest of *rrp41-1* female gametophytes at the four-nuclear stage (B, nuclei are indicated by arrowheads); (C) WT sibling of the female gametophyte shown in (B) has successfully completed development, undergone fertilization, and reached octant stage of embryogenesis (arrowhead, octant embryo). Bar, 50 μm.

(D and E) Embryo lethal phenotype of the *rrp4-1* mutant. (D) *RRP4/rrp4-1* heterozygotes produce normal and aborted seeds in 3:1 ratio. (E) Both Oy and Col-0 alleles are expressed in the WT Col-0/Oy F1 hybrid, but the Col-0-specific SNP is undetectable in the *rrp4-1*[Col-0]/Oy F1. Distal PCR primer was ^{32}P-labeled (asterisk), and RT PCR products digested with HpaII. The *rrp4-1* allele is depicted schematically, and HpaII fragment sizes indicated (in bp).

(F and G) Estradiol-triggered inducible RNAi of RRP4 and RRP41 in seedlings results in growth arrest (F) accompanied by the characteristic defect in processing of the 7S rRNA precursor into mature 5.8S rRNA (G, vertical bar).

(H and I) Venn diagram representation of the up- and down-changes in the *Arabidopsis* transcriptome in response to the depletion of RRP4 and RRP41 by iRNAi.

RRP4 (*rrp4^iRNAi*) or RRP41 (*rrp41^iRNAi*) mRNA, resulting in growth arrest (Figure 2F) and subsequent death of seedlings. Importantly, arrest was preceded by accumulation of 3′-underprocessed 5.8S rRNA species (Figure 2G). This molecular phenotype is indicative of exosome malfunction (Mitchell et al., 1997) and was never observed in WT plants exposed to estradiol (neither is growth inhibition). These results show that *Arabidopsis* RRP4 and RRP41 are essential for postembryonic growth and validate the conditional iRNAi knockdown system as a useful approach for investigating their functions in vivo.

To comprehensively identify exosome targets in *Arabidopsis* and gain additional insights into the apparent subfunctionalization of its core subunits, we implemented iRNAi in conjunction with whole-genome tiling microarrays. To minimize changes in gene expression that did not result directly from exosome depletion, we selected the earliest time point of estradiol treatment corresponding to the accumulation of underprocessed 5.8S rRNA species, but before growth retardation. Oligo(dT)-primed targets prepared from RNA samples from plants containing empty vector, *rrp4^iRNAi*, or *rrp41^iRNAi* constructs grown with or without estradiol were used to interrogate oligonucleotide tiling arrays. Therefore, the array signals should correspond exclusively to polyadenylated RNA species. Moreover, to rule out the possibility of spurious internal priming events, we employed 3′-rapid amplification of cDNA ends (3′-RACE) to map the polyadenylation sites in a subset of targets (Figure S9) as well as compared the relative change in expression between poly(A)+ and total RNA fractions for selected targets (Figures 3C, S5B, S5C, S5H, and S8).

We used the TileMap algorithm, which utilizes a two-state hidden Markov model based on probe-level t statistics (Ji and Wong, 2005), to identify genomic regions showing statistically significant changes. Expression data from arrays hybridized with targets from *rrp4^iRNAi* and *rrp41^iRNAi* plants that had been estradiol-treated were compared against the corresponding mock (DMSO)-treated samples, as well as against the empty-vector line treated with estradiol. We identified a total of 1612 genomic regions exhibiting increased levels of polyadenylated RNA upon the depletion of RRP4 (*rrp4^iRNAi*) and RRP41 (*rrp41^iRNAi*), while only about 1/10 as many regions showed downregulation (Figures 2H and 2I; Tables S2 and S3). Depleting an exoribonucleolytic complex should cause increased accumulation of its target RNAs, thus the overwhelming majority of expression changes in RRP4- and RRP41-depleted seedlings most likely represent direct effects.

In contrast, when we conducted a similar analysis of *csl4-2* mutant versus wild-type (Ws) plants, upregulation was no longer a predominant trend (Figure S2). Thus, the constitutive absence of CSL4 likely results in many secondary effects. This observation raises a general concern applicable to transcriptome studies using constitutive loss-of-function mutants and, conversely, emphasizes the value of conditional alleles like *rrp4^iRNAi* and *rrp41^iRNAi*. At the same time, it is notable that the overlap in the upregulated RNA targets

among the *csl4-2*, *rrp4^iRNAi*, and *rrp41^iRNA* samples is highly significant, while the overlap in spectra of downregulated RNAs is negligible (Figure S2). Hence, the majority of upregulated RNA targets in *csl4-2* seedlings constitute a direct molecular signature of the CSL4-less exosome. Remarkably, many of the exosome targets upregulated in *rrp4^iRNAi* and *rrp41^iRNAi* samples were unaffected in the *csl4-2* seedlings, including both nuclear-confined species (e.g., miRNA precursors, Figure 5) as well as cytoplasmic RNAs (e.g., spliced mRNAs, Figure 4). Therefore, the CSL4-less exosome is fully active on some of the exosome substrates in both cellular compartments. In addition, these data represent a valuable resource for narrowing down which of the exosome targets are essential for viability, via subtracting the *csl4-2* upregulated dataset from the *rrp4^iRNAi* and *rrp41^iRNA* analyses. For example, the 7S pre-rRNA processing defect in the *csl4-2* seedlings was as severe as in the RRP4- and RRP41-depleted seedlings (Figure 2G), and yet *csl4-2* mutant plants are phenotypically indistinguishable from WT. A global comparative overview of similarities and differences in the expression changes among the *csl4-2*, *rrp4^iRNAi*, and *rrp41^iRNA* lines can be found in Figure S2 and Tables S2–S11 and on the accompanying website (http://signal.salk.edu/cgi-bin/exosome).

The following major classes of *Arabidopsis* exosome direct targets were defined by tiling microarray analysis of *rrp4^iRNAi* and *rrp41^iRNAi* plants: (1) small nuclear RNAs (snRNAs; 9 snRNA genes from both *rrp4^iRNAi* and *rrp41^iRNAi*; Table S4); (2) the majority of small nucleolar RNAs (snoRNAs) encoded in the genome (83 and 96 snoRNA genes from *rrp4^iRNAi* and *rrp41^iRNAi* samples, respectively; Table S5); (3) a select subset of tRNA genes (20 and 14, respectively; Table S6); (4) an upregulated subset of *Arabidopsis* mRNAs (205 and 266 mRNAs, respectively; Table S7); (5) a subset of mRNAs that extend beyond their annotated 3′ end, indicative of 3′-processing defects (29 from both *rrp4^iRNAi* and *rrp41^iRNAi*; Table S8); (6) a subset of specific pri-miRNA genes (12 from *rrp4^iRNAi* and 11 from *rrp41^iRNAi*; Table S9); (7) a large class of previously uncharacterized noncoding RNAs (ncRNAs); many of these ncRNAs overlap with repetitive elements and small RNA (smRNA)-generating loci (210 and 156 ncRNAs, respectively; Table S10); and (8) a distinct class of previously undetected polyadenylated transcripts that map exclusively to the 5′ ends of known protein-coding mRNAs and hence may possess regulatory potential (52 from both *rrp4^iRNAi* and *rrp41^iRNAi*; Table S11). Notably, while the overlap in the spectra of upregulated target RNAs revealed by the depletions of RRP4 and RRP41 was highly significant (~64%), the extent of differences between them corroborates the notion of subfunctionalization of the subunits in the *Arabidopsis* exosome core (for example see Figure 4). Taken together, these results circumscribe a complex spectrum of *Arabidopsis* exosome targets that spans RNAP I, II, III, and possibly RNAP IV transcripts and includes nuclear-restricted RNAs (e.g., pri-miRNAs), cytoplasmic RNAs (e.g., spliced mRNAs), as well as RNAs distributed between the two compartments.
Figure 3. Effect of *Arabidopsis* Exosome Subunits Depletion or Mutation on rRNA Processing

(A) Effects on the sense (Watson strand) and antisense (Crick strand) rRNA-related species. Vertical bars correspond to the array probes. Boxes delimit the boundaries of the regions exhibiting prominent up- (orange and yellow) and down-changes (purple) of antisense rRNA-related transcripts.

(B) RT qPCR validation of upregulation of the IGS transcript (blue arrow in A; error bars, ±SD).

(C) Northern analysis of poly(A)+ (top) and total RNA (bottom) using the same probe as in Figure 2G reveals the accumulation of ~2.4 kb polyadenylated rRNA precursor.

RNA Targets of the *Arabidopsis* Exosome
Stable Structural RNAs

Interestingly, our array analyses identified appreciable amounts of polyadenylated RNA signals across the rDNA repeat unit even under normal conditions, which were dramatically upregulated upon depletion of RRP4 or RRP41 (Figure 3). This increased and expanded signal corresponded largely to polyadenylated pre-rRNA precursors. For example, northern analysis targeting the sequences just downstream of 5.8S rRNA revealed an increase in a polyadenylated, 3′-underprocessed species of ~2.4 kb (Figure 3C, top) that included both the 18S and 5.8S mature rRNA regions, while neither the nonpolyadenylated precursor (Figure 3C, bottom) nor the levels of mature rRNAs (data not shown) were affected. Furthermore, two major clusters of polyadenylation sites identified by 3′-RACE were both located outside of the boundaries of the mature rRNA (Figure S9). These findings parallel observations in yeast, where targeting of pre-rRNA species for degradation by the exosome is mechanistically linked
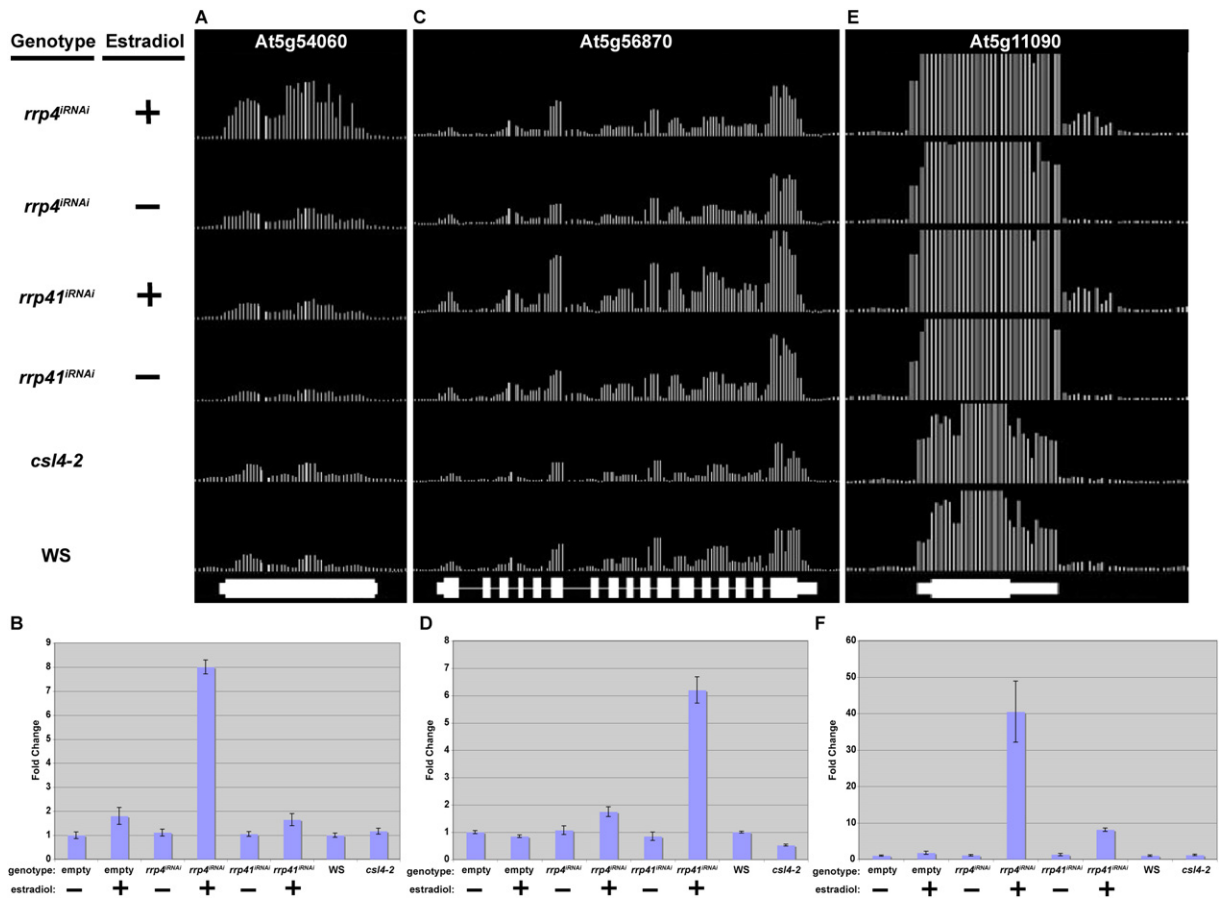

Figure 4. Effects of *Arabidopsis* Exosome Depletion on a Select Subset of mRNA

to their oligoadenylation by the TRAMP complex (Kadaba et al., 2004; Vanacova et al., 2005).

In addition, both tiling array and qPCR analyses revealed increased accumulation of poly(A)$^+$ RNAs in the intergenic spacer region (IGS, Figures 3A and 3B). Notably, in mouse cells the IGS-derived RNA regulates the activity of the main rDNA promoter in an epigenetically stable manner (Mayer et al., 2006). Interestingly, depletion of RRP4 and RRP41 also impacted the abundance of polyadenylated RNAs of antisense polarity relative to rRNAs. For example, we observed a strong increase in transcripts complementary to the external transcribed spacer and to the 5′ half of 25S rRNA. Conversely, exosome depletion led to the significant decrease of a naturally occurring antisense RNA whose boundaries closely correspond to that of 18S rRNA. Notably, this polyadenylated antisense RNA is immediately flanked by polyadenylated sense RNA, suggestive of a mutually exclusive relationship.

Moreover, in *csl4-2* seedlings, where the upregulation of the sense poly(A)$^+$ RNA in the 18S region does not occur, this antisense species is not downregulated (Figure 3A). Therefore, these findings may be indicative that rRNA C-related species are regulated by complementary antisense transcripts.

Tiling array data also revealed that depletion of RRP4 and RRP41 resulted in dramatic increases in accumulation of poly(A)$^+$ snRNAs (Table S4) and snoRNAs (Table S5), including those encoded by free-standing polycistronic clusters (Figures S5A–S5C), solitary genes (Figure S8A), as well as those embedded in introns of genes functionally related to protein synthesis (Table S5). The latter gene arrangement may help to coordinate snoRNA biogenesis with cellular demands on translation and is prevalent in animals, but it has been observed in *Arabidopsis* only once (Barneche et al., 2000). Moreover, we identified 3′-extended upregulated poly(A)$^+$ snoRNAs (Figures S5A and

S5B), which may represent either incompletely processed byproducts of snoRNA biogenesis targeted for degradation or normal processing intermediates.

Several classes of *Arabidopsis* small stable RNAs constitute previously unknown exosome substrates. One example is the RNAP III-transcribed *MRP/7-2* RNA (Figures S4E and S4F), which in yeast is processed by Rex3, not the exosome (van Hoof et al., 2000). Second, we observed accumulation of a poly(A)$^+$ form, as well as of the 3′-extended species of 7SL RNA, also an RNAP III transcript (Figures S5G–S5I and S9). Hence, the *Arabidopsis* exosome may degrade the poly(A)$^+$ 7SL RNA during RNA quality control and/or process 3′-readthrough species into mature 7SL RNA. Notably, the scattered distribution of polyadenylation sites throughout the RNA body in MRP, 7SL, U12, and U3B RNAs (Figure S9) is consistent with repeated cycles of oligoadenylation by TRAMP and exosomal "nibbling" (LaCava et al., 2005; Vanacova et al., 2005; Wyers et al., 2005). Third, we observed strong accumulation of a poly(A)$^+$ tRNA^{Tyr} (Figure S5D; Table S6), which is different from the tRNA species downregulated by the exosome and TRAMP in yeast (Kadaba et al., 2004). Biogenesis of plant tRNA^{Tyr} requires highly ordered events of $U_{35} \rightarrow \psi_{35}$ modification and splicing (Akama et al., 1997), hence this observation likely reflects the role of the exosome in proofreading of this complex process. Taken together, our observations of massive accumulation in exosome-depleted seedlings of poly(A)$^+$ forms of many stable RNAs strongly suggest that oligoadenylation coupled to exosome-mediated RNA quality control and/or processing are fundamental features of plant gene expression.

Messenger RNAs

The exosome degrades poly(A)$^-$ intermediates of mRNA decay produced by deadenylating enzymes. Poly(A)$^-$ species cannot be detected in microarray experiments using oligo(dT)-primed targets. Nevertheless, a number of upregulated signals detected in the exosome-depleted *Arabidopsis* seedlings were protein-coding mRNAs (Table S7). Notably, transcripts from intronless genes were highly overrepresented in this category (p < 0.001), suggesting a significant enrichment for processed pseudogenes. Moreover, a surprising proportion of the upregulated regions were of antisense polarity (23.3% for *rrp41*^{iRNAi} and 24.4% for *rrp4*^{iRNAi}). These findings suggest that sense and antisense poly(A)$^+$ transcripts derived from potential pseudogenes in *Arabidopsis* are specifically and directly targeted for exosome-mediated 3′–5′ decay.

Interestingly, a number of mRNAs targeted by the *Arabidopsis* exosome exhibit subunit-specific responses (Table S7). For example, the level of a putative glycosyltransferase mRNA (*At5g54060*) is increased upon the depletion of RRP4 but not of RRP41, while the opposite is true for a putative β-galactosidase mRNA (*At5g56870*; Figures 4A–4D). While the mechanistic basis of differential sensitivity to the depletion of RRP4 or RRP41 remains to be determined, these examples parallel their distinct mutant phenotypes and corroborate the notion of subfunctionalization of the *Arabidopsis* exosome core subunits.

Unexpectedly, tiling array experiments also revealed a number of mRNAs with extended 3′ ends but whose absolute levels were unaffected (Table S8; Figures 4E and 4F). This may be indicative of *Arabidopsis* exosome-mediated degradation of aberrant readthrough mRNAs although we cannot rule out the alternative possibility that the exosome participates in 3′ end formation of some mRNAs.

Intermediates of microRNA Biogenesis

Depletion of RRP4 and RRP41 also revealed significant increases in pri-miRNA transcripts (Table S9; Figure 5). Interestingly, the increased signal was mostly located upstream of the stem-loop structure that harbors the miRNA/miRNA* duplex, while the downstream segments were usually unaffected (Figure 5A), and the levels of mature miRNAs were also unchanged (Figure 5C). In addition, our analyses revealed novel polyadenylated intermediates corresponding to the region between the miRNA and miRNA* (Figures 5D, S6B, and S9). Together, these findings delineate a 3′–5′ pathway of removal of upstream and middle (loop) byproducts involving TRAMP-like and exosome activities (Figure S6A). Although these exosome-dependent reactions do not appear rate limiting for biogenesis of mature miRNAs, they likely facilitate efficient recycling of the pre-miRNA processing factors. Surprisingly, our 3′-RACE analyses of the upregulated signal in the pri-miRNA168a transcript demonstrated that in the majority of cases (72%) polyadenylation occurred immediately upstream of the mature miRNA sequence (Figures 5B and S6C), indicating that pri-miRNA168a is often cleaved directly at the precursor/miRNA boundary. These findings are inconsistent with the proposed two-step pathway of plant miRNA biogenesis via an initial processing of pri-miRNA into pre-miRNA, followed by processing of pre-miRNA into mature miRNA (Kurihara and Watanabe, 2004), and suggest the existence of possible alternative pathways.

Heterochromatic Repeat-Associated and Novel Noncoding RNAs

Additionally, tiling microarray experiments revealed the accumulation of numerous poly(A)$^+$ transcripts that have neither protein-coding potential nor predicted functions. Significantly, a large fraction of these RNA species escaped detection in previous transcriptome analyses (Meyers et al., 2004; Yamada et al., 2003), apparently because their steady-state levels in WT plants are tightly downregulated via exosome-mediated degradation (Table S10). Notably, there was a highly significant overlap among these RNAs in *rrp4*^{iRNAi}, *rrp41*^{iRNAi}, and *csl4-2* samples (Figure S2C). Remarkably, these novel exosome-specific RNAs exhibit a strikingly nonrandom association with small RNA-producing loci, as well as with repeated sequences: 72% from *rrp4*^{iRNAi} and 63% from *rrp41*^{iRNAi} (p < 0.001; Figures 6A and 6B). Furthermore, we often observed the accumulation of complementary RNAs of both polarities (Figures 6C and 6E). Another characteristic
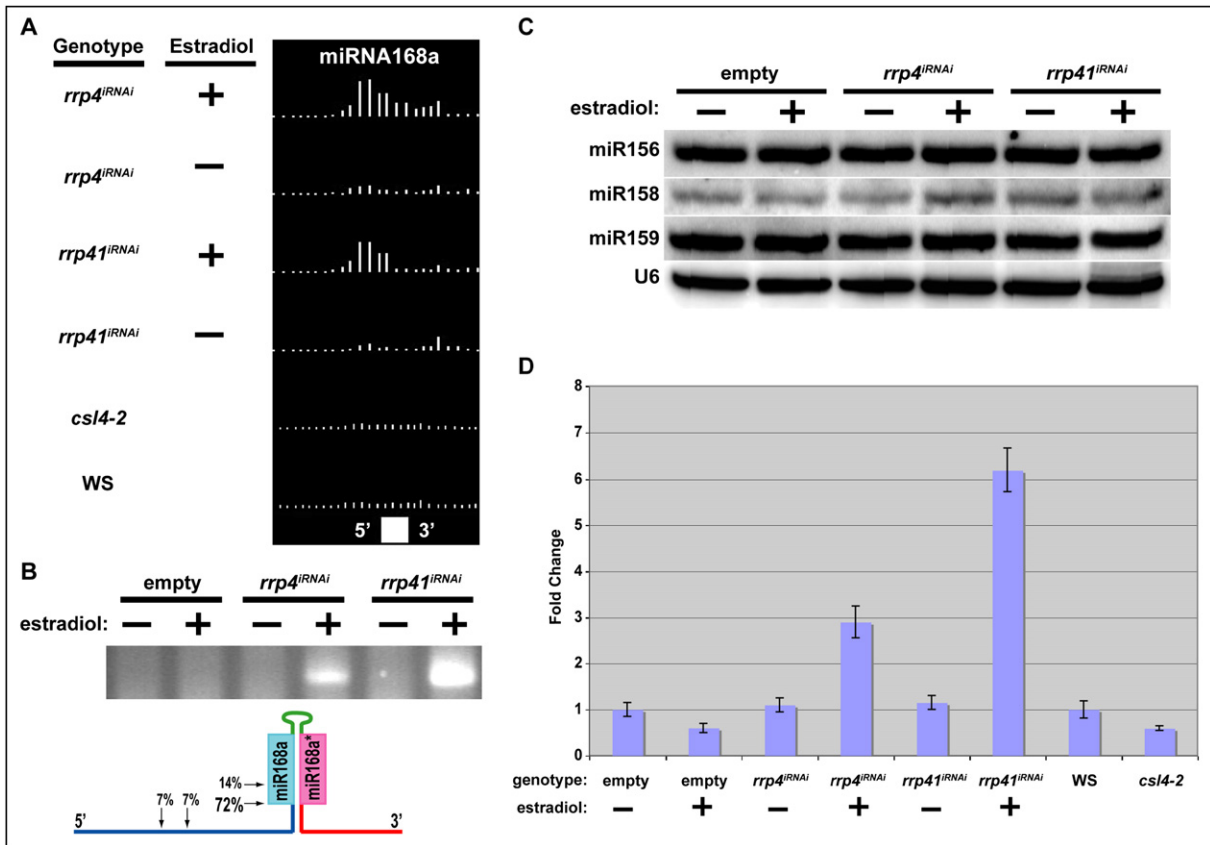

Figure 5. Effects of Exosome Subunit Depletion on pri-miRNA Processing Intermediates

(B) 3′-RACE of pri-miRNA168a; distribution of 3′-endpoints of the sequenced 3′-RACE products are shown in the bottom panel.

(C) Northern blot analysis demonstrates that mature miRNA levels are not affected by exosome depletion.

(D) Oligo(dT)-primed RT qPCR targeting the loop region of pre-miR156e. Error bars, ±SD.

example concerns an exosome-specific sense/antisense transcript pair emanating from a repetitive sequence element containing 42 bp interspersed tandem subrepeats (Figure 6G). Such sense/antisense transcript pairs serve as precursors for the ~24 nt endogenous heterochromatic small-interfering RNAs (siRNAs) that guide RNA-dependent DNA methylation (RdDM) and H3K9 methylation of transposon and tandem repeat loci (Cao et al., 2003; Lippman and Martienssen, 2004; Xie et al., 2004; Zilberman et al., 2004). Therefore, we confirmed the increased expression of the 5S rDNA region that gives rise to siRNA1003 in RRP4- and RRP41-depleted seedlings, as well as csl4-2 mutant plants (mature 5S rRNA levels were unaffected; Figures 6C and 6D). Notably, the novel exosome-specific ncRNAs are preferentially associated with centromeric and pericentromeric regions of the *Arabidopsis* genome highly coincident with repetitive elements and DNA methylation (Zhang et al., 2006), while exosome-regulated mRNAs are excluded from these regions (Figure 6H). Hence, the *Arabidopsis* exosome may have a general role in quality control of RdDM-associated siRNA biogenesis precursors and/or degrade

heterochromatin-associated RNAs, as shown for heterochromatic silencing of select loci in *S. pombe* (Bühler et al., 2007). Overall, these data suggest that the *Arabidopsis* exosome plays an important role in regulating heterochromatin-associated transcripts.

Another remarkable example of a novel ncRNA upregulated upon exosome knockdown was an ~4 kb long transcript lacking significant protein-coding capacity but conserved in closely related dicots (e.g., *Capsella rubella*, Figures 7A–7C). Curiously, sequence conservation between the *Arabidopsis* and *Capsella* transcripts is confined to two interspersed short direct repeats 16 nt and 24 nt in length (Figures 7B and S7), suggesting that these small conserved segments constitute its functionally important elements. For example, they might serve as recognition sites for RNA-binding proteins or be processed out to form small RNAs. These repeated segments do not reside in secondary structures resembling DICER substrates, thus their processing would likely have a distinct mechanistic basis.

Perhaps the most intriguing category of exosome targets was a distinct subclass of ncRNAs colinear with the
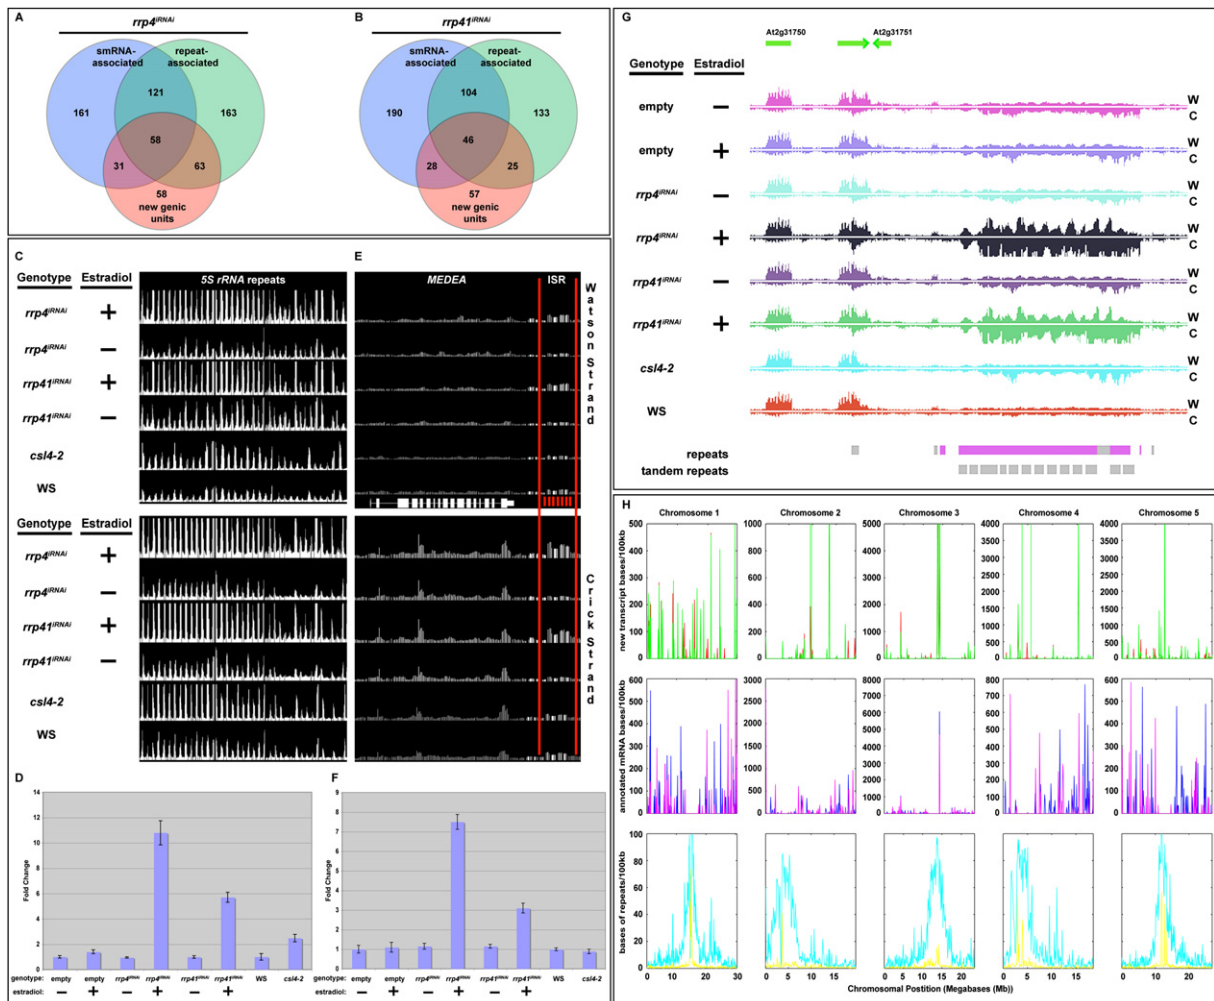

Figure 6. Effects of Exosome Subunit Depletion or Mutation on Novel Transcripts Associated with siRNAs and Repetitive Elements

(A and B) Venn diagram representation of upregulated, exosome-specific transcripts and their highly significant association with smRNA-generating loci and repetitive elements. As shown in the Venn diagrams, the majority of transcripts that are only observed upon exosome depletion are associated with smRNA-generating loci and/or repetitive elements (72% for *rrp4*[iRNAi] and 63% for *rrp41*[iRNAi] lines).

(C–F) Upregulation of transcripts encoded on both strands of tandem repeats. (C and D) Polyadenylated 5S transcripts: (C) tiling microarray data, (D) RT qPCR results. Note the 500 bp periodicity in the tandem repeat signals in (C). (E and F) Polyadenylated transcripts from the MEA-ISR repeats (red boxes). Error bars, ±SD.

(G) An example of an upregulated, exosome-specific transcript (screenshot from the exosome-regulated transcriptome database, http://signal.salk. edu/cgi-bin/exosome). W and C indicate signal from Watson and Crick strands of the *Arabidopsis* genome. Repetitive element is denoted by purple bar, with its constituent 42 bp tandem repeats indicated by the dark gray boxes.

(H) Chromosomal distribution of novel upregulated, exosome-specific transcripts. Top panels demonstrate the total length of novel upregulated, exosome-specific transcripts (y axis, left-side scale) in a sliding 100 kb window in *rrp4*[iRNAi] (green line) and *rrp41*[iRNAi] (red line) treated with estradiol. Middle panels show the total length of annotated mRNAs upregulated upon estradiol treatment of *rrp4*[iRNAi] (purple line) and *rrp41*[iRNAi] (blue line) plants. Bottom panels demonstrate the total lengths of all repeats (light blue line) and tandem repeats (yellow line) in a sliding 100 kb window.

5′ ends of known protein-coding transcripts (Table S11 and Figures 7D and 7E). We propose that the origin of these ncRNAs (hereafter called upstream noncoding transcripts, or UNTs) is distinct from that of the overlapping "main" RNAP II transcription units. First, they are unlikely to be derived from cytoplasmic mRNA degradation because the exosome enters the decay pathway after mRNA deadenylation and degrades the mRNA body processively in a 3′–5′ direction. Hence, exosome depletion

would cause an accumulation of deadenylated, full-length transcripts and/or heterogeneous populations of 3′-truncated poly(A)$^-$ fragments with endpoints scattered throughout the mRNA body (Anderson and Parker, 1998). In contrast, the UNTs are collinear only with the 5′ ends of known mRNAs (Figure S9). Also, UNTs frequently extend into the first intron of respective overlapping genes. The possibility that UNTs derive from the pre-mRNAs is highly improbable, particularly when the UNT
Figure 7. Examples of Novel Noncoding RNAs Revealed by Tiling Microarray Analyses of *Arabidopsis* Exosome Depletion

(A–C) Upregulation of a ~4 kb long transcript containing internal short interspersed repeats conserved in *Capsella rubella*. (A) Tiling microarray data.

(D and E) Example of the strongly upregulated upstream noncoding transcript (UNT) in the 5′ region of *At1g20100* in the exosome subunit-depleted seedlings. (D) Tiling microarray data. (E) Northern blot analysis of poly(A)⁺ RNA.
(F) Results of the RT qPCR. Error bars, ±SD.

is more abundant than the corresponding mRNA (Figures 7D and 7E).

The striking association of *Arabidopsis* UNTs with the 5′ ends of RNAP II transcription units must reflect some aspect of their biogenesis or function. Several features

of UNTs are reminiscent of cryptic unstable transcripts (CUTs) in yeast, which are present at very low levels in WT cells (Wyers et al., 2005). CUTs are frequently associated with promoters of protein-coding genes, and while some may merely reflect transcriptional noise, others

may also have biological functions (Davis and Ares, 2006; Kopcewicz et al., 2007). Moreover, recent detailed mapping of the human transcriptome also revealed an abundant class of promoter-associated short (up to 200 nt) ncRNAs, termed PASRs (Kapranov et al., 2007), which also may act as negative regulators of the main transcription units (Martianov et al., 2007). Although UNTs may differ from both CUTs and PASRs because their 5′ ends appear to coincide with those of the main RNAP II transcripts (Figures 7D and S9), our results suggest that the exosome-regulated ncRNAs associated with 5′ ends of genes likely represent a fundamental regulatory feature of eukaryotic transcriptomes.

Conclusion

We combined genetic, proteomic, and whole-transcriptome analyses to investigate the function of the exosome complex in the multicellular eukaryote *Arabidopsis thaliana*. We find that individual subunits of the plant exosome are functionally specialized, ranging from being dispensable for growth and development (CSL4) to being essential for the development of female gametophytes (RRP41) or embryogenesis (RRP4). Moreover, the plant exosome complex lacking its CSL4 subunit is partially intact and functional. These findings demonstrate an unexpected degree of functional plasticity in the plant exosome core. Our whole-genome tiling array analyses revealed numerous novel exosome substrates, new metabolic aspects of several known important RNA species, a broad role of the exosome in regulation of ncRNAs associated with heterochromatic regions, as well as the widespread occurrence of polyadenylation- and exosome-mediated RNA quality control in plants. Furthermore, our findings reveal a "deeply hidden" layer of the transcriptome composed of intergenic noncoding transcripts that are tightly downregulated by constitutive exosome activity. Finally, a publicly available exosome-regulated transcriptome database (http://signal.salk.edu/cgi-bin/exosome) should aid in illuminating new fundamental components and regulatory mechanisms in complex eukaryotic transcriptomes.

EXPERIMENTAL PROCEDURES

Plant Material and Reverse Genetics

Mutant alleles *csl4-1* and *csl4-2* correspond to SALK_004561 (Alonso et al., 2003) and FLAG_055B05 lines, respectively. The *rrp4-1* allele is SALK_025995, *rrp41-2* and *rrp41-3* are SALK_139189 and SALK_112819, respectively, while *rrp41-1* was isolated from the University of Wisconsin BASTA population. WT plants of matching accessions were used in all reciprocal crosses (Col-0 for all Salk alleles and Ws for FLAG and University of Wisconsin alleles). For complementation with the WT and TAP tagged transgenes, respective heterozygotes were transformed (Clough and Bent, 1998) and the progeny plants lacking the WT allele and containing both the T-DNA insertion allele and the transgene identified by PCR.

Proteomics

TAP purification protocol was adapted from Rigaut et al. (1999). The Coomassie-stained protein bands were treated with trypsin using an In-Gel Digestion kit (Pierce), and dried peptides dissolved in 50%

acetonitrile, 0.1% trifluoroacetic acid with 5 mg/ml alpha 4-hydroxy-cinnamic acid as a matrix. 0.6 μl of peptide/matrix mix was loaded onto the 6AB MALDI sample plate, dried, and subjected to MALDI-TOF MS and subsequent MS/MS analyses using the 4700 Proteomics Analyzer and GPS software (Applied BioSystems). A combination of peptide mass fingerprinting (PMF) and MS/MS sequencing analysis was performed using the Mascot search engine. Fragmentation of the precursors was carried out using the collision-induced dissociation (CID). CID spectra were submitted for protein identifications with a precursor precision tolerance of 1 Da and MS/MS fragment tolerance of 0.5 Da. A criterion of correct protein identification was a confidence interval exceeding 95%, which was a combination of protein scores from PMF and ion scores from MS/MS sequencing.

Inducible RNAi

RNAi cassettes contained 940 bp (*RRP4*) or 788 bp (*RRP41*) fragments of the target cDNA sequence as a pair of inverted repeats, separated by the *FAD2* intron in the pER8 vector backbone (Zuo et al., 2000). For iRNAi, seedlings were germinated and grown for ≤7 days on 8 μM of 17β-estradiol.

RNA Analyses

Polyacrylamide Northern blot analyses were performed as described (Chekanova et al., 2000). Transcripts were quantified by RT qPCR using the comparative threshold cycle method ($\Delta\Delta C_t$, primers listed in Table S16), using Actin 3 (At3g53750) as endogenous reference.

RNA Extraction, Probe Synthesis, Microarray Hybridization, and Analysis

Fifteen micrograms of total RNA extracted using TRIzol (Invitrogen) was used to synthesize double-stranded cDNA using the GeneChip One-Cycle cDNA Synthesis Kit (Affymetrix). Biotin-labeled cRNA was generated using the GeneChip IVT Labeling Kit and fragmented, and 15 μg of cRNA was hybridized to *Arabidopsis* tiling arrays (Zhang et al., 2006). Hybridization, staining, and washing were performed according to the Affymetrix Eukaryotic Target Protocol. A minimum of two biological replicates were performed for each of the three genotypes, the empty vector (referred to as WT for brevity), *rrp4*^{iRNAi}, and *rrp41*^{iRNAi}, using estradiol or control (DMSO) treatment. The TileMap tiling array analysis software package (Ji and Wong, 2005) was used to detect statistically significant differences in transcriptional activity in the tiling microarray data as described in Zhang et al. (2006) and further detailed in the Supplemental Data.

Supplemental Data

Supplemental Data include Experimental Procedures, nine figures, and eighteen tables and can be found with this article online at http://www.cell.com/cgi/content/full/131/7/1340/DC1/.

Supplemental Experimental Procedures

TAP tagging constructs

A ~300bp fragment containing pea *rbcS-E9* polyadenylation signal was PCR-amplified with primers oDB607+oDB626 (all primers used in this study are listed in Table S18), which introduced the Sal I and Pst I restriction sites at the ends of the amplicon, and cloned into pCAMBIA1300, resulting in pDB588. *Arabidopsis* genomic fragments containing the RRP4 (1.9 kb, primers oDB611+oDB612) or RRP41 (3.4 kb, primers oDB617+oDB618) were amplified and fused by overlap extension to the TAP tag sequence, which was amplified from pBS1479 (Rigaut et al., 1999) with oDB608+oDB609 (for RRP4) or oDB608+oDB610 (for RRP41). Resulting inserts were digested with BamH I and Sal I (for RRP4) or BamH I and Xho I (for RRP41) and cloned into pDB588 linearized by BamH I + Sal I, producing pDB589 (RRP4-TAP) and pDB591 (RRP41-TAP).

Inducible RNAi constructs

Inducible RNAi constructs were created using following steps. First, the Fad2 intron was amplified from genomic DNA using oDB731 and oDB732, cleaved at PspOM I and Eag I sites added into the 5'-parts of the PCR primers, and cloned into pTA211 (Sanchez and Chua, 2001), selecting direct orientation clones using diagnostic PCR with oDB725 + oDB732. In the step 2, the resulting construct (pDB608) was used to insert the sense segment of the respective RNAi cassette (amplified with oDB749 and oDB750 in case of RRP4, or with oDB727 and oDB728 in case of RRP41) in front of the Fad2 intron, using Asc I and Bsr GI restriction sites. In the step 3, the same segments of respective RNAi cassettes, amplified with the same primers as above (oDB749 and oDB750 in case of RRP4 or with oDB727 and oDB728 in case of RRP41), were cloned downstream of the Fad2 intron after digesting the PCR products with PspOM I and Asc I and digesting the vector with PspOM I and Mlu I. Finally, the whole cassette (Gene-of-interest-sense / Fad2 intron / Gene-of-interest-antisense) was transferred into pER8 (Zuo et al., 2000) as Asc I - Pac I fragment. In the resulting final constructs, the respective iRNAi cassettes are located downstream of the minimal 35S promoter containing eight LexA operators, and is in the same T-DNA with the gene encoding G10-90 promoter-driven chimeric transactivator XVE and hygromycin resistance marker.

Purification of the Arabidopsis exosome complex

TAP protocol was adapted from (Rigaut et al., 1999), with the extraction buffer modified according to (Witte et al., 2004). Frozen above-ground *Arabidopsis* tissue (50 g for preparative scale experiments) was ground to fine powder using mortar and pestle at the temperature of liquid nitrogen, mixed with equal (w/v) amount of extraction buffer (0.1 M Tris-HCl pH 8.0, 150 mM NaCl, 5 mM each of EDTA and EGTA, 10 mM DTT, 0.5% Triton X-100 and protease inhibitor cocktail) and allowed to thaw at room temperature. Slurry was further pulverized using Polytron (PowerGen) at a maximal setting for 3-5 min and additionally sonicated on ice using 3 X 30 sec bursts. Extract was clarified by 30 min centrifugation at 20,000 g, filtered through two layers of miracloth, supplemented with 10% v/v glycerol and stored at -80°C. For exosome purification, extract (45 ml) was mixed with 5 ml of prewashed IgG agarose beads (Amersham) and incubated for 4 hr at 8°C with end-over-end rotation. Resin was transferred into a glass column, washed with 4 X 30 ml wash buffer (50 mM Tris-HCl pH 8.0, 150 mM NaCl, 5 mM each of EDTA and EGTA, 2 mM DTT, 0.05% Triton X-100) and equilibrated with 2 X 30 ml washes with TEV buffer (50 mM Tris-HCl pH 8.0, 150 mM NaCl, 5 mM EDTA, 2 mM DTT, 0.05% Triton X-100). Cleavage was initiated by resuspending the resin in 12.5 ml of TEV buffer supplemented with 1000 U of TEV protease (Invitrogen) and a cysteine protease inhibitor E-64 (Sigma) in excess of 10μM. Cleavage was allowed to proceed overnight at 8°C on rotating wheel. The column was drained, supernatant diluted 3 X with the calmodulin binding buffer (50 mM Tris-HCl pH 8.0, 150 mM NaCl, 1 mM imidazole, 1 mM MgOAc, 2 mM $CaCl_2$, 10 mM β-mercaptoethanol and 0.05% Triton X-100), and supplemented with 75 μl of 1M $CaCl_2$. The mixture was then transferred into a 50 ml tube containing 5 ml of prewashed calmodulin resin (Stratagene) and incubated for another 3-4 hours on rotating wheel at 8°C. The slurry was transferred into a glass column, drained, and resin washed by 2 X 5ml of calmodulin binding buffer. We found the EGTA elution of calmodulin resin-bound complexes largely ineffective, and that high concentration of Triton X-100 impede downstream concentration and electrophoresis steps. Consequently, elution was conducted using the modified alkaline buffer (50 mM Tris-HCl pH 8.0, 150 mM NaCl, 25 mM NaOH, 1 mM imidazole, 1 mM MgOAc, 5 mM EGTA, 10 mM β-mercaptoethanol and 0.01% Triton X-100). This allowed a rapid and quantitative release of the CBP-tagged proteins in just one column volume. Collected fractions were immediately neutralized by the addition of an equal volume of acidic buffer (150 mM Tris-HCl pH 8.0, 150 mM NaCl, 1 mM imidazole, 1mM MgOAc, 25 mM HCl, 10 mM β-mercaptoethanol), and concentrated using a microconcentrator with a 10 kDa cutoff (Vivascience). Proteins obtained from RRP4-TAP, RRP41-TAP and WT *Arabidopsis* extracts were run side-by-side using 15% SDS-PAGE and stained using a colloidal Coomassie kit (Invitrogen).

Fractionation of the extracts by glycerol gradient sedimentation

Extracts from 2 to 4 g of Ws or *csl4-2* seedlings were prepared by grinding snap-frozen tissue in liquid nitrogen followed by the extraction with 3 volumes of buffer containing 50 mM Tris-HCl pH 7.9, 150 mM NaCl, 5mM $MgCl_2$, 5 mM each of EDTA and EGTA, 10 mM DTT, 0.1% Nonidet-P40 and the protease inhibitor cocktail (Sigma #P9599, 1:100 diliution). After clarifying by centrifugation at 16,000g, 300 μl of each extract was loaded onto a 12 ml linear 10-30% glycerol gradient prepared in the same buffer. Extracts were fractionated by sedimentation at 36, 000 rpm for 24 hours in the SW-41 rotor using Beckman Optima L-90 K preparative ultracentrifuge, with molecular weight standards were fractionated in parallel (BSA, 66 MW kDa; alcohol dehydrogenase, 141 kDa; β-amylase, 210 kDa; horse spleen ferritin, 443 kDA; and bovine thyroglobulin, 669 kDa). Twenty four 0.5 mL fractions were collected using AutoDensiFlow fractionator (Labconco) and 30 μl of each fraction was analyzed by Western blotting with affinity-purified polyclonal antibodies against the RRP41 subunit of the *Arabidopsis* exosome (Chekanova et al., 2000).

Cytology and microscopy

Ovules were fixed in Carnoy's solution (glacial acetic acid:absolute alcohol, 1:9) overnight, and subjected to alcohol washes (80% and 70%, 30-60 min each). The 70% alcohol was replaced by

clearing solution (chloral hydrate: H_2O: glycerol, 8:2:1) for ≥ 60 min. Cleared samples were observed under DIC optics using either Leica DMR or Olympus BX60 microscope.

Identification of differentially expressed regions using tiling microarrays

The TileMap package, originally developed for ChIP-on-chip analysis (Ji and Wong, 2005), can also be applied to detect and compare the transcription activity in tiling microarray data (e.g. (Zhang et al., 2006)). The Tilemap algorithm does not combine and treat all the probes in a particular gene together, but instead treats every probe as a separate entity. Hence, this software does not report a gene-level measurement of expression changes, but produces an unbiased identification of any genomic regions that may correspond to exon(s), intron(s), intergenic region(s) etc., showing significant up- or downregulated expression.

The data for the three genotypes included in this analysis, the empty-vector control line (subsequently referred to WT for brevity), *rrp4*[RNAi] and *rrp41*[RNAi], the two treatments, estradiol and DMSO as control (subsequently referred to as +/- estradiol for brevity), and the chips corresponding to the two DNA strands, Watson and Crick, were processed as follows. Microarray feature intensities for both replicates for the given knockdown line, both with and without estradiol treatment, and the WT control treated with estradiol were quantile normalized and subjected to a multi-comparative TileMap analysis. For example, in the case of *rrp4*[RNAi], the data for a total of six tiling arrays (e.g., 2 replicates for WT treated with estradiol, 2 replicates for *rrp4*[RNAi] treated with estradiol, and 2 replicates for *rrp4*[RNAi] not treated with estradiol) from one strand were all quantile normalized at the same time. Differentially expressed regions were then identified by comparing the WT sample treated with estradiol and *rrp4*[RNAi] both with and without estradiol treatment, for both Watson and Crick strands. This generated two lists: (1) *rrp4*[RNAi] treated with estradiol > WT treated with estradiol PLUS *rrp4*[RNAi] treated with estradiol > *rrp4*[RNAi] not treated with estradiol, and (2) *rrp4*[RNAi] treated with estradiol < WT treated with estradiol PLUS *rrp4*[RNAi] treated with estradiol < *rrp4*[RNAi] not treated with estradiol. The posterior probability setting of 0.7, within a maximal region of 100 bases, was used in these analyses. The *rrp4*[RNAi] treated with estradiol > *rrp4*[RNAi] not treated with estradiol comparison identifies regions with increased expression due to knockdown of Rrp4 protein levels, and the *rrp4*[RNAi] treated with estradiol > WT treated with estradiol comparison removes regions with increased expression only due to estradiol alone. The analyses for the *rrp41*[RNAi] samples were done in the same way. The resulting lists of the RNA targets identified by these analyses are given in the Table S2, and the combined summary of the resulting data is shown in main Figure 2I. The analysis of the representation of the various Gene Ontology (GO) categories among the exosome targets was conducted using GeneTools (Beisvag et al., 2006).

To estimate the false positive rate arising due to any transcripts in *Arabidopsis* that may be inducible or repressible by the estradiol per se, both replicates for WT sample with and without estradiol treatment (i.e., 4 arrays for the Watson strand and 4 arrays for the 4 Crick strand) were quantile normalized and subjected to TileMap analysis. Differentially expressed regions were identified by generating lists (WT with estradiol > WT no estradiol and WT treated with estradiol < WT with no estradiol) at posterior probability 0.7 within a maximal region of 100 bases, i.e. the same parameters as used for the comparisons of the knockdown lines above. This analysis yielded no differentially expressed regions. Moreover, even at a lower posterior probability value of 0.5, only six genomic regions could be identified (one up-regulated and five down-regulated), all on the Crick strand. Therefore, at the stringency of the statistical employed in this work, any effects of estradiol alone can be considered negligible.

Figure S1. Characterization of the Arabidopsis *csl4* mutant alleles.

(A) Positions of the T-DNA insertions relative to the *CSL4* gene structure in the *csl4-1* and *csl4-2* mutant alleles (T-DNAs are indicated in red, *CSL4* exons are shown in blue, and UTRs are marked in gray).

(B) RT-PCR experiment demonstrating the complete absence of the *CSL4* mRNA in the *csl4-2* mutant plants (data for four *csl4-2* plants are shown, #133, 135, 137 and 138). RT-PCR amplification of the *RRP41* mRNA from the same plants was used as positive control.

Figure S2. Transcriptome-wide expression changes in the *csl4-2* mutant seedlings.

Venn diagram representation of up- and down-changes in the *Arabidopsis* transcriptome in response to the inactivation of the *CSL4* exosome subunit gene, as compared to the changes observed upon the *RRP4* (*rrp4^{iRNAi}*) or *RRP41* (*rrp41^{iRNAi}*) depletion. Seedlings of the *csl4-2* mutant (as well as of the Ws accession, as genotype-matched WT control) were harvested for RNA extraction at the same stage of development as for the *RRP4* (*rrp4^{iRNAi}*) or *RRP41* (*rrp41^{iRNAi}*) depletion analyses.

(A) Up-changes in the *csl4-2* seedlings, identified using stringent TileMap settings (3 probes with a maximal gap of 100 bases and posterior probability of 0.7), exhibit a highly significant overlap with the up-changes observed in the *RRP4* and *RRP41* depletion experiments.

(B) On the other hand, the down-changes in the *csl4-2* seedlings are much more extensive than in the *RRP4* and *RRP41* depletions, moreover, they do not overlap significantly with the expression changes observed in the *RRP4* and *RRP41*-depleted seedlings.

(C) Importantly, the extent of overlap among the populations of exosome-specific transcripts (i.e. RNAs that are undetectable unless the exosome activity is compromised) that are upregulated in the *csl4-2* mutant vs. *RRP4* and *RRP41*-depleted samples is highly significant.

Figure S3. Arabidopsis *rrp41* mutant alleles and their transmission in reciprocal crosses.

(A) Positions of the T-DNA insertions in *rrp41-1, -2* and *-3* mutants. Locations of the PCR primers used for testing the transmission of WT and *rrp41-1* mutant alleles shown in (B) are indicated.

(B) Multiplex PCR to simultaneously detect both WT and the *rrp41-1* mutant allele shows that the *rrp41-1* allele is transmitted normally through the male (top) but is not transmitted through the female parent (bottom). WT and *rrp41-1* mutant allele-specific PCR products and the respective primer pairs are indicated on the right.

Figure S4. Characterization of the *rrp4-1* mutant allele and its phenotype.

(A) Positions of the T-DNA insertion in *rrp4-1* mutant.

(B-E) Range of phenotypes observed in the *rrp4-1* mutant seeds. Panels (B) through (D) represent the mutant and panel (E) represents WT seeds from the same silique derived by self-pollination of *RRP4/rrp4-1* heterozygote. Microscopy was performed on cleared whole-mount seeds. (B) Arrested seed containing abnormal bicellular embryo (marked by arrowhead), endosperm is missing; (C) Arrested seed with abnormal bicellular embryo (arrowheads) and apparently normally developing endosperm (End); (D) Arrested seed with abnormal globular embryo (Emb), endosperm is missing; (E) Normaly developing WT seed with the early heart-shaped embryo (Emb) and alveolar endosperm (End) from the same silique as

the arrested seeds shown in panels (B) through (D).

(F,G) Characterization of the developmental arrest stage of the *rrp4-1* mutant seeds using reporter transgenes. (F) The *FAE1::GUS* transgene (Rossak et al., 2001) is expressed in near-mature WT embryo but not the sibling *rrp4-1* mutant globular embryo (arrow) from the same silique that was derived by self-pollination of *RRP4*/*rrp4-1* heterozygote. (G) The *DCL1::GUS* transgene (Golden et al., 2002), which is turned off in the WT seeds at the globular stage, is still expressed in the *rrp4-1* mutant embryo (arrow) when it is already turned off in the WT sibling embryo from the same silique derived by self-pollination of *RRP4*/*rrp4-1* heterozygote.

Figure S5. Effects of the *Arabidopsis* exosome sububits depletion or mutation on stable structural RNAs.

(A-C) Upregulation of the snoRNA29.1_30_31 cluster visualized by tiling microarray hybridization (A), RT qPCR (B) and Northern blot analysis (C). Blue, green and red colors in (A) and (B) correspond to the three primer pairs whose positions are indicated by arrows in (B). Note that the upregulated signal extends beyond the mature 3' end of the snoRNA31 (red circle in A, red bars and red down-arrow in B).

(D) Upregulation of the polyadenylated form of tRNA^{Tyr} visualized by tiling microarray hybridization.
(E, F) Upregulation of the polyadenylated form of the MRP/7-2 RNA visualized by tiling microarray hybridization (E) and RT qPCR (F). Error bars, ±SD.

(G-I)   Alterations in 7SL RNA metabolism visualized by microarray hybridization (G) and Northern blot analysis of poly(A)$^+$ RNA (H, top) and total RNA (H, two bottom panels). New RNA species were revealed using a generic 7SL oligo probe and the 3' extension-specific 7SL probe are indicated by black and red arrows, respectively. (I) Cryptic RNAP III terminators found downstream of the *Arabidopsis* 7SL genes. Sequences immediately downstream of the annotated 3' ends (arrowhead) of 7SL transcripts were aligned with ClustalW. Runs of four or more T residues, known to serve as efficient RNAP III terminators (Allison and Hall, 1985; Lin-Marq and Clarkson, 1998; Platt, 1986; Yukawa et al., 2000), are shaded gray. 7SL RNA gene names are from (Yukawa et al., 2000)).

Figure S6. Effects of the exosome complex on the pri-miRNA processing in Arabidopsis.

(A)   Proposed pathway of pri-miRNA processing with an emphasis on the exosome-mediated steps. Pri-miRNA undergoes endonucleolytic cleavages catalyzed by DCL1 in conjunction with the dsRNA binding protein HYL1 and possibly additional auxiliary factors (X?). Cleavages occur at several sites, as indicated by stars. According to the accepted model, initial cleavages occur near the base of the stem (blue stars), however, our 3' RACE experiments (panel C) show that, at least in the case of miR168a, the majority of the upstream cleavage sites map at the position directly abutting the miRNA/miRNA* duplex. Therefore, the pathway is drawn to also account for the possibility of direct processing at the boundaries of miRNA/miRNA* duplex (orange stars). The released miRNA/miRNA* duplex undergoes 3'-end methylation by HEN1, exported out of the nucleus, and assembles into the RISC complex to carry out its biological function. On the other hand, the released 5', loop and 3' segments of the precursor must be degraded, and the factors bound to them recycled for their use in the future rounds of pri-miRNA processing. The 5' and the loop segments are oligoadenylated, presumably by a TRAMP-like activity, and targeted for degradation by the exosome complex. The 3' segment is likely degraded by a 5'-3' exonuclease, possibly XRN4.

(B)   Sequence alignment of the miR159a 3'-RACE clones demonstrates clustering of the polyadenylation points in the loop region of pri-miRNA159a. Yellow and green shading correspond to the miR159a* and miR159 sequences, respectively.

(C)   Sequence alignment of the 3'-RACE clones of the released 5' segment of the pri-miR168a precursor

(see also the main Figure 5D). The lengths of the poly(A) tails are given in the right column. Green lettering indicates nonA residues. The poly(A) tail boundary, indicated by red lettering, reports the position of the cleavage of the pri-miR168a precursor by DCL1. Note that the majority of such cleavage events directly abut the beginning of the miR168a sequence (red arrow); only two clones (rrp4_3.19 and rrp41_3.14) show cleavages at upstream positions.

Figure S7. Internal substructure of the large noncoding RNA conserved in *Arabidopsis thaliana* and *Capsella rubella*.

ClustalW alignments of the short internal subrepeats present in the *Arabidopsis* and in the *Capsella rubella* noncoding transcripts described in the main Figure 7. "Blue" and "red" color-coding of subrepeats corresponds to the schematic and the dotplot shown in Figure 7B. Subrepeats are numbered consecutively from the 5' to the 3' end of the 4 kb *Arabidopsis* transcript. The blue subrepeat occurs twice and the red subrepeat occurs once in the ~400 nt *Capsella* transcript.

In the case of the blue subrepeat (top box), shading indicates the 8 nt core that is 100% conserved in the 23 *Arabidopsis* subrepeats and in the two *Capsella* subrepeats. In the case of the red subrepeat, light gray shading indicates regions of ≥80% conservation. The four positions demonstrating 100% identity between the *Capsella* version of the red subrepeat and all 21 *Arabidopsis* subrepeats are indicated by darker shading and blue lettering.

Figure S8. Magnitude of relative expression changes in the poly(A)$^+$ vs. total RNA fraction varies with the relative abundance of respective exosome targets.

The ratio of upregulation of the respective exosome target in the poly(A)$^+$ RNA (fold) divided by the upregulation of the same target observed in the total RNA (fold) is shown in the right column.

(A) Results of Northern blot analysis of the highly abundant U3 snoRNA in poly(A)$^+$ vs. total RNA.

(B) Results of the qRT PCR analysis of the level of the moderately abundant 7SL RNA using oligo(dT)-primed and random primed cDNA.

(C) Results of the qRT PCR analysis of low-abundance noncoding RNA described in the main Figure 7, using oligo(dT)-primed and random primed cDNA and a different primer pair (oDB1196/oDB1197).

Figure S9. 3'-RACE mapping of the polyadenylation sites in RRP4- and RRP41-depleted lines

Black diamonds correspond to the positions of the individual sequenced poly(A) tails identified by the 3'-RACE in the rRNA repeat (blue arrow denotes IGS; mature 18S, 5.8S and 25S rRNA species are indicated), U12 snRNA, U3B snoRNA, 7SL RNA, MRP/7-2 RNA, pre-miR159a (positions of the miRNA159a* passenger strand and the mature miRNA159a within the stem-loop precursor are indicated in yellow and blue, respectively), pre-tRNA^{Tyr} (the pre-tRNA^{Tyr} intron is indicated in green) as well as a UNT derived from the At1g20100 locus. In the case of the locus At1g20100 UNT, the positions of the 5'ends identified by the 5'-RACE from the RRP41-depleted seedlings are also indicated (blue triangles).
